Introduction

Persistent racial and ethnic gaps in educational achievement have focused policy attention on school climate and safety as important elements of educational performance. In a special issue of *Educational Researcher* focused on safety and order in schools, Cornell and Mayer (2010) argue that school safety and school order are fundamental to studies of the achievement gap, teacher attrition, and student engagement. This paper represents the first large-scale analysis of how feelings of safety at school affect educational outcomes. If student safety affects achievement there may be educational benefits of policies aimed at improving safety and order in schools and classrooms.

Academic attainment is a critical step toward future success in adult life, increasing employment and earnings and the probability of other stabilizing life events such as marriage. Studies show that early childhood test scores are positively correlated with future labor market outcomes (Currie & Thomas, 1999). Yet, black and Hispanic students consistently underperform on standardized tests compared to white and Asian students (U.S. Department of Education, 2004, 2008). These racial gaps persist even as test scores have risen for all students. Gaps in achievement extend to college enrollment and completion rates and as a result, whites are more than twice as likely to earn a bachelor's degree as blacks (Western, 2006). Educational gaps translate into differences in wealth accumulation over the life-course, differing rates of marriage (Schneider, 2011), and disparities in future health outcomes (Freudenberg & Ruglis, 2007; Fiscella & Kitzman, 2009). Lower educational attainment is associated with an increased probability of arrest and incarceration: the risk of imprisonment is five times greater for black men with no college degree compared to white men with the same level of education (Lochner &

Moretti, 2004; Western, 2006). Identifying the factors that contribute to these gaps is critical to narrowing disparities in later-life outcomes.

Relevant Literature

A safe environment is a prerequisite for productive learning (Maslow, 1970; Piaget, 1936). If students feel unsafe at school, they may be less likely to go to school at all, or less able to focus on learning while at school. Feeling unsafe in the classroom specifically may decrease concentration in class and performance on assessments. However, only a few studies have focused on the contribution of feelings of safety in the school environment to educational achievement. Henrich and colleagues (2004) surveyed a sample of New Haven middle schools students and found that exposure to community violence is related to academic achievement and overall feelings of safety at school. However, the authors do not discuss the relationship between feeling unsafe at school and academic outcomes, and are unable to control for unobserved individual characteristics that might explain both feelings of safety and achievement. In his work on school discipline, Arum (2003) determines that feelings of safety at school are positively related to both behavioral and academic outcomes. He finds variation in the relationship between school safety and academic outcomes by gender, with feelings of safety having larger positive association with test scores for females than males, and larger positive association with behavior (i.e. decreases in fighting) for males than females.

If students feel unsafe at school, one response may be to stay home. Therefore, increased school absences may be the primary path through which feeling unsafe affects academic outcomes. Although many studies assert that missing school affects students negatively, few have empirically investigated the impact of being absent on academic achievement. Existing studies show that low student participation in class predicts school absences (Finn & Cox, 1992)

and absenteeism is related to lower achievement (Monk & Ibrahim, 1984) and a higher probability of dropping out (Rumberger, 1995). However unmeasured student characteristics, such as motivation, may explain the identified relationships between participation, absences, and achievement. A notable contribution to the literature is Gottfried's (2010) work identifying the relationship between attendance and achievement in elementary and middle schools in Philadelphia. Using detailed student-level data and a school and classroom fixed effects approach, Gottfried finds that attendance and achievement are positively related.

A related body of research investigates how school and neighborhood crime and disorder effect achievement. Exposure to neighborhood violence affects students' academic performance and that of their peers (Aizer, 2008; Carrell & Hoekstra, 2010; Delaney-Black et al., 2002; Gibson, Morris, & Beaver, 2009; Ripski & Gregory, 2009; Sharkey, 2010; Sharkey, Schwartz, Ellen, & Lacoe, 2014). Studies relying on student or principal reports find that violence within schools reduces school attendance, increases misbehavior, and reduces the likelihood of high school graduation and college attendance (Bowen & Bowen, 1999; Chen, 2007; Grogger, 1997). Peer disorder, such as bullying, is negatively related to school safety and achievement and is also associated with more serious school violence (Akiba, 2010; Arseneault et al., 2006; Buhs, Ladd, & Herald, 2006; Glew et al., 2005; Juvonen, Wang, & Espinoza, 2011; Schwartz, Gorman, Nakamoto & Toblin, 2005; Skiba et al., 2004). In fact, these less serious incivilities are stronger predictors of feelings of safety at school than violent crimes or personal experiences of crime (Mayer, 2010; Skiba, Simmons, Peterson, & Ford, 2006).

Research about racial and ethnic test score gaps identifies school and neighborhood contexts as sources of differences in test scores, but few studies have been able to adequately measure these contextual factors (Fryer & Levitt, 2004). Research in progress provides evidence that

black and Hispanic students are more likely to report feeling unsafe in the classroom than white or Asian peers who attend the same schools and share the same classrooms (Author, 2012). Factors related to these racial gaps in safety include disciplinary fairness, school disorder, and racial tension. Research has also documented racial disparities in the use of school discipline, with higher rates of office referral, suspension, and expulsion for black students (Skiba et al., 2002), and in perceptions of disciplinary fairness (Arum, 2003; Kupchik & Ellis, 2008). Racial gaps in discipline may be directly linked to achievement gaps, because suspensions decrease academic performance for black middle and high schools students and contribute to late graduation and dropout (Davis & Jordan, 1994; Raffaele Mendez, 2003). Differences in disciplinary environments across schools may contribute to racial gaps in achievement, with black high school students achieving higher test scores in schools with more discipline (Arum & Velez, 2010). In fact, gaps in performance are found between black and white students in high schools where students view the disciplinary scheme as unfair and lenient, whereas no racial differences are found in schools where discipline is perceived as strict and fair (Arum, 2003). Although there is a growing body of evidence about how exposure to violence and disorder affects students, and about racial and ethnic disparities in school discipline, we know less about the mechanisms that connect these phenomena to academic achievement. Feeling unsafe in the classroom is one way that these factors may affect student performance.

This paper improves upon the previous literature in four important ways. First, I exploit a large, longitudinal data set of information about students, including their feelings of safety and perceptions of violence and disorder at school, linked to administrative academic records. The dataset represents a sample size that is many times larger than previous studies. Second, whereas most of the existing literature summarized above are concerned with overall school safety, this

paper focuses on how safe students feel in the classroom, specifically. Feelings of safety in the

classroom may differ from safety in other parts of the school, given the presence of a teacher and

the dynamics within the classroom, and may be more directly linked to achievement. Third, I

provide insight into the causal relationship between feeling unsafe in the classroom and

academic performance through a variety of econometric methods and multiple robustness

checks. Finally, the findings are situated within the context of current policies and programs

aimed at improving school safety and security.

Purpose and Hypotheses

The central question addressed in this paper is: Does feeling unsafe in the classroom affect

student academic performance? Based on Maslow's hierarchy of needs which places safety

above only breathing, food, and water (Maslow, 1970) and evidence that neighborhood

conditions such as community violence affect children's cognitive ability (i.e. Sharkey, 2010), I

hypothesize that feeling unsafe in the classroom will negatively affect student performance on

standardized assessments. There may be both a direct effect of feeling unsafe on test scores, and

an indirect effect (see Figure 1). Feeling unsafe in the classroom may directly affect test scores if

it inhibits learning or distracts students as they take exams. However, feeling unsafe may also

affect academic achievement indirectly through increased absences, if feeling unsafe increases

the likelihood that a student stays home out of fear. I test both the direct and indirect effects of

reported feelings of safety on test scores to identify whether the impact of feeling unsafe operates

solely through increased absences, or whether feeling unsafe exerts a unique effect on

achievement in addition to any effect on absences.

[Figure 1]

Method

Data

Student surveys are the primary source of information for researchers and policymakers about violence and safety in the nation's schools (Skiba et al., 2006). In 2007, the New York City Department of Education implemented a school environment survey for all students in sixth grade and above. The annual survey asks a series of questions about student engagement, school climate, and safety. This analysis is based upon student-level survey data for the 2006-7 through 2009-10 school years. Over 80 percent of the middle school student in the district responded to the survey in more than 700 public schools and 10,000 homerooms. The survey data is matched to individual administrative education records from the Department of Education, providing a rich set of covariate and outcome measures, including the number of absences per year and standardized test scores.[1]

Response Rates and Survey Reliability

The quality of research based on anonymous survey data rests on the validity and reliability of the reported information. Due to the high coverage of the student population in grades six and above, the results of this study are generalizable to the population of surveyed students in New York City. While response rates vary across schools (Figure 2), the overall response rate is very high (above 80 percent). Descriptive analyses indicate that there are differences between students who take the survey and those who do not. Although respondents and non-respondents are

---

[1] The survey data are matched to the administrative records using a unique scrambled student identifier provided to the researcher by the Department of Education. The match is conducted by school year. The scrambled identifier allows researchers to observe students over time (i.e. use student fixed effects) as well as match additional Department of Education data to the administrative records, without revealing names or birthdates of individual students.

comparable in many ways, non-respondents have lower test scores on average than respondents.[2] These differences are potentially problematic if the students who do not respond to the survey have systematically different feelings of safety than respondents. Non-response could bias the results in either direction depending on whether non-respondents feel more or less safe than respondents.

[Figure 2]

I conduct two tests of the construct validity of the safety measures used in this study. First, for respondents, there is a strong correlation between reporting frequently staying home due to feeling unsafe at school and actual school absences recorded by the school, indicating that safety has important implications for attendance rates.[3] Students who feel the least safe may have more absences which make them more likely miss school when the survey or the standardized test is administered. As a result, the findings presented here may be underestimates of the true impact of feeling unsafe at school on test scores.

As a second test, student perceptions of social disorder are compared to school-level administrative measures of school violence reported on an annual basis through the New York State Violent and Disruptive Incident Reporting (VADIR) system.[4] Figure 3 shows that student-reported violence and disorder varies in the expected direction with the level of school violence reported through the VADIR, indicating that students in the most violent schools report higher levels of disorder.

---

[2] Percentages of students who are female, enrolled in ESL, native born, and receiving free or reduced price lunch are comparable between respondents and non-respondents. Black and Hispanic students make up larger percentages of the non-respondent group than the respondent group. (Contact author for table).

[3] Students who stay home because they feel unsafe have 2.6 more absences on average, than students who do not.

[4] Schools are categorized by quartiles based on the number of incidents that occur in a given year: "Low" = 25th percentile and below; "Mid" = between 25th and 50th percentiles; "Mod" = between 50th and 75th percentiles; "High" = 75th percentile and above.

[Figure 3]

Issues of reporting accuracy, particularly under-reporting or over-reporting on sensitive topics, could be a concern for research about feelings of safety. For instance, social pressures may make it likely for middle school students, particularly boys, to under-report feeing unsafe at school. In this case, significant effects of feeling unsafe on academic outcomes would be conservative estimates. Even with the likelihood of under-reporting, the survey data show that among middle school students in New York City, boys are more likely to report that they feel unsafe than girls.

Sample

The sample is restricted to students in the 6, 7, and 8 grades for three primary reasons. First, survey response rates are highest for students in these grades (compared to high school grades), ensuring better coverage of the population of middle school students. Second, nationally, a larger share of middle school students report being bullied compared to high school students.[5] This is confirmed in the New York City data, as feelings of safety in the classroom vary by grade level: the share of student that feels unsafe peaks in the 7th and 8th grades and declines as students enter high school. Therefore, safety may affect test scores for the largest number of students in the middle grades. The third reason pertains specifically to the context of this study. In New York, high school students do not take the state standardized exams and instead take a series of subject-area exams throughout their high school tenure, making it difficult to model test score changes between middle and high school. Finally, to ensure sufficient variation within schools and classrooms, schools with fewer than 10 respondents, and classrooms with fewer than 4

---

[5] See Table 11.1 in the U.S. Department of Justice, Bureau of Justice Statistics, School Crime Supplement (SCS) to the National Crime Victimization Survey, 2011.

respondents are omitted from the analysis. The final sample includes survey responses for more than 340,000 individual students, over multiple years.

Measures

The main focus of this paper is safety in the classroom, given the link between the classroom setting and academic performance. While feeling unsafe throughout the school may affect student achievement, feeling unsafe in the classroom may directly affect academic performance if a student is unable to absorb material during instruction or to focus during test administration. Responses to the four-response scaled survey item "I am safe in my classes" are re-coded as binary, taking a value of one if the student "disagrees" or "strongly disagrees" with the statement. Whether a student feels safe or unsafe is more salient for this analysis than the marginal difference between students who "disagree" or "strongly disagree" with the statement, which would require strong assumptions about individual interpretations of these categories.[6] Using the same approach, I also construct measures of reported feelings of safety in the hallways, bathrooms, and locker rooms, and safety outside the school on school grounds. The final safety measure captures the frequency with which a student chooses to stay home because he or she feels unsafe at school. Students respond to the statement "I stay home because I don't feel safe at school" with the frequency response options "never", "some of the time," "most of the time," and "all of the time." This measure is coded as a binary variable taking the value of one if the student stays home out of fear "most" or "all" of the time.

The primary outcome measure, academic achievement, is parameterized by scores on an annual state math exam, standardized as z-scores by year and grade. To ensure temporal precedence, impacts are only estimated for math exam scores, because the math exams were

---

[6] Models disaggregating the "disagree" and "strongly disagree" responses are presented as a robustness check.

administered after the student survey. During most of the study period, the English exams were administered prior to the school survey. The measure of school absences is the natural log of the number of full days absent in the past year. Some models also include individual student characteristics, including special education status, free or reduced price lunch status, whether the student speaks a language at home other than English, gender, race, and ethnicity. These indicator variables take the value of one if the characteristic is present for the student. Additionally, the models control for total school enrollment because students in smaller schools have been found to report higher levels of safety at school (Arum, 2003).

Method

Baseline Model

The impact of feeling unsafe on academic achievement is estimated using a series of regression models. The first specification (equation 1) presents the baseline model of the relationship between feeling unsafe in the classroom (*UnsafeClass$_{it}$*) and math test scores (*TestScore$_{it}$*),

(1) $TestScore_{it} = \beta_0 + \beta_1 UnsafeClass_{it} + \gamma grade * year_t + \varepsilon_{it},$

where *grade*year$_t$* is a set of dummy variables controlling for annual time trends at the grade level. However, individual student characteristics may explain both feeling unsafe in the classroom and achievement. The second specification (equation 2) includes a vector of observed student characteristics (*IndChars$_{it}$*),

(2) $TestScore_{it} = \beta_0 + \beta_1 UnsafeClass_{it} + \delta IndChars_{it} + \gamma grade * year_t + \varepsilon_{it},$

that includes special education status, free or reduced price lunch status, language spoken at home other than English, gender, and race and ethnicity. These models also include annual school enrollment to control for the effect of attending a larger school.

Strengthening the Baseline Model

There are several methodological challenges to isolating the impact of feeling unsafe on academic achievement. A main concern is omitted variable bias which could occur because school or classroom characteristics, such as the school environment or a particular teacher, affect both feelings of safety and academic achievement. If important variables are omitted from the model, changes in academic outcomes may be inaccurately attributed to students' feelings of safety. As shown earlier, a larger share of students who attend more violent schools report feeling unsafe, compared to students who attend less violent schools. To strengthen the model, school fixed effects are added to control for characteristics of the school environment, such as violence and disorder, which may affect feelings of safety.

However, students may be exposed to different classroom environments within the same school. In more disorderly classrooms, teachers may themselves be fearful, or may dedicate more time to discipline at the detriment of instructional time. Students in these classrooms may suffer academically as a result. Therefore, the next model includes homeroom fixed effects, controlling for unobserved, time-invariant characteristics of homerooms that likely affect safety and achievement. Although the within-homeroom comparisons do not control for tracking into higher or lower level courses (that may foster safety differently), these models allow for a comparison between students who experience the same classroom environment at least once during the school day.

Still, unobserved *individual* factors may be explaining student feelings of safety and academic achievement among students in the same homerooms. To strengthen the individual controls in the model, two approaches are taken. First, a value-added model is estimated in which the individual student's test score from the previous year is added to the homeroom fixed effects

model. In a value-added model, an individual's achievement in a given year is a function of all previous years of schooling and experience. The value-added model estimates the effect of feeling unsafe in the classroom on the gain in test scores over the prior year alone, removing differences between students that have accumulated over years of schooling. [7]

Although it is an improvement over the previous model, the value-added model does not control for all time-invariant characteristics of an individual student that may be related to safety. Student fixed effects estimators are widely used in the literature about value-added models of education to achieve causal estimates of the impact of a policy change on student achievement (Gentile & Imberman, 2011). Therefore, the second approach is to control for unobserved student characteristics that remain constant over time in a student fixed effects model. This model also includes controls for school-specific year effects to capture the influence of shocks to the entire school – such as a new principal, or adoption of a new academic policy – that might affect both student safety and test scores.

Prior research has documented differences in feelings of safety at school between black and white students, Hispanic and white students, and boys and girls (e.g., Alvarez & Bachman, 1997; Arum, 2003; Hong & Eamon, 2011; Schreck & Miller, 2003). To investigate whether the impact of feeling unsafe in the classroom on academic outcomes differs by these characteristics, the student fixed effect model includes interactions between feeling unsafe in the classroom and race, ethnicity, and gender indicators.

---

[7] There is no clear standard in the literature about specification of value-added models. Most researchers use a cumulative model which estimates the impact of inputs on the level test score controlling for prior scores, or a gain score model which uses the change in test score from the previous year as the dependent variable (Gentile & Imberman, 2011; Harris & Sass, 2006; Rockoff, 2004; Rothstein, 2009; Wiswall, 2011). Another approach is to measure the contemporaneous effect of inputs on test scores using the student fixed effect alone to capture prior performance (Harris & Sass, 2006; Wiswall, 2011). Value-added models are inconsistent when estimated using a random effects estimator, therefore a fixed effects estimator is used (Harris & Sass, 2006).

To test the direct and indirect effects of feeling unsafe in the classroom, I add a measure of whether a student reports staying home from school due to feeling unsafe and a measure of the number of absences that occurred in the given year to test the moderating effect of absenteeism.

Validity Tests

Despite the strategies described above, there may remain a concern that systematic, time-varying individual or school characteristics not included in these models are driving both feelings of safety and academic achievement. Potential sources of omitted variable bias include changes in the home lives of individual students or general school "disorder" that might both cause students to feel unsafe and perform poorly on tests. If school disorder affects both feelings of safety and test scores – by making students feel physically unsafe, or by distracting the teacher during instruction – these models may incorrectly attribute the effect of disorder on academic performance to feelings of safety. To isolate the impact of feeling unsafe on achievement from the other ways in which school disorder may affect test scores, I test the impact of alternative measures of safety at school that are less directly related to academic performance. If these measures of safety are also significant predictors of achievement, it is more likely that an omitted variable is causing students to feel unsafe across all contexts and their academic achievement to decline.

In addition to omitted variable bias, another threat to the validity of the causal inference is reverse causality – an inability to determine the direction of causality between feeling unsafe at school and having poor academic performance. This can result in correlation between the independent variables in the model (i.e. feeling unsafe) and the error term, violating a condition of unbiased OLS estimation. The econometric models presented thus far have been based on prior research that finds exposure to violence negatively affects the academic achievement of

students and their peers (Carrell & Hoekstra, 2010; Sharkey, 2010). If students exposed to violence become fearful, they may misbehave in class and disturb their own learning and that of their peers, or they may stop coming to school altogether. If this is the case, one would expect the relationship to operate from feelings of safety to academic outcomes. However, one could tell a different, but plausible, story. Students who are falling behind in school may fear disappointing their teachers or being embarrassed in front of classmates, and may feel that the classroom is not a safe or comfortable place. In this case, poor academic performance may drive feelings of safety at school. On the other end of the spectrum, strong academic performance may be associated with feeling unsafe at school if high-performing students are targeted for bullying. To address the simultaneity concern, the analysis is restricted to standardized tests that are given *after* the survey is administered, and I conduct a falsification test of the impact of feeling unsafe in future years on current test scores.

After isolating the relationship between classroom safety and academic performance and determining the direction of causality, I explore variation in the impact estimate across schools with different levels of school violence.

Results

Students who report feeling unsafe in the classroom experience a consistent, negative effect on test scores. The finding is robust to school, homeroom, and student fixed effects models. Robustness and validity checks support this central finding.

Descriptive Statistics

Fifteen percent of all middle school students report feeling unsafe in the classroom.[8] Students who report feeling unsafe have different average characteristics than students who report feeling safe in the classroom (Table 1). Although a majority of students qualifies for free or reduced price lunch, a proxy for poverty, students who report feeling unsafe are more likely to be poor.[9] Males make up a larger share of students who report feeling unsafe in the classroom than females, and a larger share of black students report feeling unsafe than white, Asian, and Hispanic students. Students who feel unsafe in the classroom are more likely to qualify for special education services, compared to students who feel safe.

[Table 1]

Students who report feeling unsafe in the classroom have higher mean absences and lower scores on the math and English language arts standardized tests. The share of students who take standardized tests is high across all response categories (97 percent), tempering any concerns about systematic differences in test taking. While the average student across both safety responses is in a school that is majority same race or ethnicity, students who report feeling unsafe in the classroom go to schools where a larger share of peers report that social disorder – bullying, fighting, and gang activity – is a problem in the school.

Reporting feeling unsafe in the classroom is correlated with reported feelings of safety in other areas of the school. Approximately 80 percent of students who feel unsafe in the classroom also feel unsafe in the hallways, bathrooms, and locker rooms, and 77 percent also feel unsafe outside the school on school grounds, compared to 19 percent of students who feel safe in the

---

[8] Share of students by response to statement "I feel safe in the classroom": Strongly agree (37%), Agree (43%), Disagree (10%), Strongly Disagree (5%), No response (6%).

[9] Unsafe includes the responses "disagree" or "strongly disagree" to the statement "I feel safe in the classroom."

classroom but unsafe in the halls, and 26 percent of students who feel safe in the classroom but unsafe outside the school. Most notably, 15 percent of students who feel unsafe in the classroom also report that they stay home most or all of the time because they feel unsafe at school. Only 3 percent of students who feel safe in the classroom report staying home out of fear at similar levels. While classroom safety is indeed related to feelings of safety elsewhere in the school, the unique relationship between students and teachers inside a classroom and the direct link between classroom learning and achievement through testing conditions (as opposed to other school climate factors which may be less directly linked to achievement or test-taking), make classroom safety a particularly important dimension of safety to consider.

Overall, students who respond to the survey but do *not* answer the safety questions appear to be similar to the least safe students. Compared to students who responded, larger shares of non-respondents are poor (70 percent), speak a language at home other than English (59 percent), and are enrolled in special education (17 percent). A larger share of the students who did not respond is black (39 percent). The mean number of absences and the mean reading and math scores for students who did not answer the safety questions are on par with or lower than students who report feeling the least safe. These statistics indicate that students who did not answer the classroom safety question are most similar to those students who feel the least safe at school; therefore the estimates of the impact of feeling unsafe on test scores may be underestimates.

How safe students feel changes over time (Table 2). Of the students who reported feeling the least safe in the classroom in a prior year (strongly disagree), 38 percent continue to feel unsafe in the following year, while 57 percent report feeling safe in the classroom in the following year

(and 5 percent are missing responses to the safety question).[10] Of the students who feel the least safe in the current year, 25 percent changed their response from "strongly agree" in the previous year, 37 percent changed their response from "agree" from the previous year, 20 percent changed their response from "disagree" in the previous year, and 18 percent did not change their response. There does not seem to be a pattern of non-response linked to prior year response – if anything, of the students missing responses to the survey in the current year, over 80 percent reported feeling safe in the classroom in the prior year.

[Table 2]

Regression Results

The baseline specifications presented in Table 3 show consistent evidence that feeling unsafe in the classroom decreases test scores. This finding is robust to the addition of individual covariates, school and homeroom fixed effects, and inclusion of the prior year test score. The raw correlation between reporting feeling unsafe and test scores is a 0.32 standard deviation decrease in scores. The effect size is reduced significantly with the addition of individual covariates (0.23), school fixed effects (0.13), and homeroom fixed effects (0.09). The value-added specification (column 5) shows that reporting feeling unsafe in the classroom decreases math test scores by 0.06 standard deviations, controlling for prior test scores, homeroom effects, and grade level time trends. This effect size is larger than the independent effect of being poor on test scores (0.02). In column 6, the effects of "strongly disagreeing" and "disagreeing" are

---

[10] That reported safety varies across the middle school years is not surprising. Simple descriptive statistics show that a larger share of students reports feeling unsafe in the classroom in 7th and 8th grade, compared to 6th grade. If students are more likely to become involved in delinquent activities (smoking, fighting, etc.) or with delinquent peers as they get older, they may also be more likely to report feeling unsafe. Although boys are more likely to report feeling unsafe at school than girls, this may also change with age, puberty, and maturity.

estimated separately, with the expected pattern of a stronger expression of feeling unsafe related to a larger decrease in test scores (0.07).

[Table 3]

Still, individual level omitted variables may explain the relationship between feeling unsafe and achievement. Controlling for time-invariant student characteristics further reduces the size of the effect of feeling unsafe (Table 4). The first student fixed effects model shows that feeling unsafe in the classroom results in a 0.04 standard deviation decrease in test scores. The specification in column 2 includes annual school trends to control for school-wide changes that might affect test scores and safety (such as a new principal, or change in disciplinary or security policy). With these controls, on average, a student who reports feeling unsafe in the classroom experiences a 0.03 standard deviation decrease in math test scores.[11]

[Table 4]

Although the descriptive statistics show that a greater share of black and Hispanic students feel unsafe in the classroom compared to white and Asian students, interaction models show no differences in the rate at which reporting feeling unsafe affects test scores by student race and ethnicity (contact author for table). One might assume that boys entering middle school are more likely to become involved in delinquent behavior, making them feel more fearful and also negatively influencing their academic achievement. On the contrary, the results show no differential effect of changes in feelings of safety in the classroom on test scores between boys and girls.

---

[11] The third specification estimates the effect of a change in response to a more "unsafe" category over time, regardless of whether it is a change from very safe to safe or from unsafe to very unsafe, and finds that overall, each decrease in reported feelings of safety results in a 0.02 standard deviation decrease in test scores.

Staying home from school out of fear is one mechanism through which feeling unsafe in the classroom may affect test scores. On average, students who indicate that they stay home because they feel unsafe at school should have a higher number of absences. As a validity check of this measure of safety, Table 5 presents the relationship in a regression framework. There is a strong association between staying at home due to feeling unsafe and the log of full day absences. The association persists with the inclusion of individual student characteristics, school and classroom fixed effects, and student fixed effects. Within the same classrooms, students who report staying home because they feel unsafe have 15 percent more absences, on average, than students who do not (specification 4).

[Table 5]

The results in Table 6 show that holding reported feelings of safety in the classroom constant, students who indicate that they stay home because they feel unsafe at school experience a larger decrease in test scores (an additional 0.03 standard deviation decrease).[12] Each additional absence from school also decreases test scores. In fact, there is no independent effect of staying home due to feeling unsafe at school when an interaction term between staying home and absences is included in the model (column 3). The point estimate on classroom safety is largely unaffected by the inclusion of these additional measures, indicating that there is both a direct effect of feeling unsafe on academic achievement and an indirect effect through increased absences.

[Table 6]

Validity Tests

---

[12] The measure includes students who said that they "most" or "all" of the time stay home because of feeling unsafe.

It is possible that unobserved, time-varying student characteristics may explain both feelings of safety and test scores, or that potential simultaneity prevents the identification of a causal relationship. Although there is no surefire way to alleviate this concern in the quasi-experimental context, several validity tests provide support that the estimates are causal.

For the first validity test, I estimate a model including alternative measures of feelings of safety in school that are less closely related to academic performance. If feeling unsafe in all contexts affects test scores, it is more likely that an omitted variable that is affecting safety and achievement is present and causing bias in the results. For instance, the victimization of a family member through domestic violence may influence both feelings of safety and performance in school. However, one would expect that this type of violence exposure would make students feel unsafe in all contexts, not just in the classroom. Table 7 provides the results from variants of the student fixed effect model that include feeling unsafe in the hallways, bathrooms, and locker rooms at school, and feeling unsafe outside the school on school grounds. There is no relationship between these measures of safety and test scores when controlling for safety in the classroom, and the magnitude and significance of the effect of feeling unsafe in the classroom is unchanged.[13] Although this test does not rule out all potential sources of omitted variable bias, it minimizes the threat to internal validity since remaining omitted variables affecting test scores should be related to feelings of safety in the classroom only.[14]

---

[13] Feeling unsafe in the halls, and outside the school, are significantly related to test scores in models that omit feelings of safety in the classroom.

[14] I also investigate whether differential exposure to neighborhood crime is explaining the relationship between safety and achievement that I observe. I estimate a series of models using the annual number of crimes that occur in each student's census tract of residence as a measure of neighborhood crime. The inclusion of the neighborhood total crime level does not affect the magnitude or significance of the coefficient on feeling unsafe in the classroom in specifications with homeroom fixed effects or student fixed effects. Further, interaction terms between feeling unsafe in the classroom and neighborhood crime are not statistically significant in any of the models. This provides

[Table 7]

Second, as a falsification check, I test whether feelings of safety in the *following* year predict test scores in the current year (Table 8). No relationship is found between future safety and current test scores, and the coefficient on the current year safety measure is unchanged. Future reported feelings of safety do not affect test scores in the previous year, suggesting that changes in reported feelings of safety are driving decreases in test scores, not the reverse.

[Table 8]

The findings are also robust to estimation on a smaller, balanced panel of students who respond to the survey for all three years of middle school (Table 9). The coefficient on feeling unsafe in the classroom maintains significance and the point estimate from the balanced panel model is larger than the estimates achieved using the unbalanced panel.

[Table 9]

As a final robustness test, I estimate variations on the value-added model, including a model with a lagged test score but no student fixed effects (as employed by Gottfried, 2010), a student fixed effect model with level scores and then with lagged scores, and a model of the change in test score as the dependent variable (Table 10). The point estimate and significance of the variable of interest is larger for the first specification, indicating that a value-added approach alone is no substitute for a student fixed effect estimator. Across the student fixed effect models, the estimates for feeling unsafe in the classroom are robust to estimation with just the level math score and no lagged score, and estimation on the change in math score.

[Table 10]

_____

evidence of an independent effect of feeling unsafe in the classroom on test scores, even after controlling for neighborhood crime and the interaction term between unsafe in class and crime. Tables available from the author.

Variation in the Impact Estimates

Finally, I investigate the variation in the impact estimates by levels of school violence to learn whether the impact of feeling unsafe on test scores is larger for students who are exposed to more school-based violence. Descriptively, it appears that the average student in a school with high violence feels less safe than the average student in a low violence school. Differences in the violent incident rate in the school may result in larger impacts of feeling unsafe in the classroom on academic outcomes. Table 11 presents the student fixed effect models stratified by quartiles of school violent and disruptive incident rates in 2007 (the baseline year of the survey).[15] Column 1 estimates the impact of feeling unsafe in the classroom on math scores for students who attend schools that had the lowest incident rates in the city in 2007, and column 4 presents the impact estimate for students attending schools that had the highest incident rates. The models also control for the change in the incident rate between 2007 and 2010, and total enrollment in the school, as well as grade and year fixed effects. Results show that feeling unsafe in the classroom has no statistically significant effect on test scores for students in the lowest violence schools, but as students are exposed to greater in-school violence and disruption the impact estimates grow larger and become statistically significant. For students in schools with the highest violent and disruptive incident rates, the impact of feeling unsafe in the classroom is a 0.033 standard deviation decrease in math performance.

[Table 11]

Discussion

This study provides the first large-scale estimate of the impact of feeling unsafe in the classroom on academic achievement, and indicates that there is a consistent negative effect of

---

[15] School-based violent and disruptive event rates are based on the statewide Violent and Disruptive Incident Report (VADIR).

feeling unsafe in the classroom on math test scores in the most controlled, student fixed effects model. Put differently, students who report feeling the safest in their classes, and who report never staying home because they feel unsafe at school perform higher, on average, on standardized math exams.[16] To put this effect size in context, previous research has found that an effect size of 0.03 standard deviations on a standardized assessment for elementary and middle school students is roughly equivalent to one additional month of instruction in a school year (Hill, Bloom, Black & Lipsey, 2008).[17]

While an estimated decrease in math scores due to feeling unsafe in the classroom of 0.03 standard deviations is a small effect, it is within the range of effect sizes resulting from interventions specifically aimed at improving achievement.[18] A study of the impact of classroom size on test scores finds that small class sizes – an intervention widely adopted across the country – increases test scores by 0.05 to 0.10 standard deviations (Stretcher & Bohrnstedt). Other research on class size has found effects of similar magnitudes (Chubb & Loveless, 2002). Further, in an analysis of the impacts of small class size on test scores using Tennessee STAR data, Krueger (1999) estimates that an increase of 1 standard deviation in either math or reading test scores translates into 8 percent higher earnings, on average, over the life course. Although there is little comparable research in the violence and school safety literature, a paper estimating

---

[16] Student fixed effect models of the impact of feeling safe in the classroom find a 0.038 standard deviation increase in math scores when students "strongly agree" with the statement "I feel safe in my classes", and a 0.025 increase when students "agree" with the statement, relative to when they disagree or strongly disagree. Similarly, it is only when students report "never" staying home because they feel unsafe at the school that they experience benefits in terms of test scores (relative to staying home "all of the time.").

[17] Effect size calculated by the Strategic Data Project at Harvard University, in a report titled "SDP Human Capital Diagnostic for Los Angeles Unified School District," November 14, 2012, based on the empirical findings of Hill, Bloom, Black & Lipsey (2008).

[18] Randomized studies have found variation in the size of educational intervention effects by grade level and test type, with mean effect sizes for younger students on broad standardized tests being lower on average than for older students (Hill et. al., 2008).

the effect of exposure to homicides finds small but highly significant effects on children's cognitive functioning (Sharkey, 2010). Indeed, safety is one of many factors contributing to student academic success. These findings suggest that policy efforts to improve school safety may yield small gains in achievement, in addition to other benefits of a safe school environment.

Prior work has found that black and Hispanic students systematically report feeling less safe in the classroom than their white and Asian peers, even when they share the same schools and homerooms (Author, 2012). Overall, a larger share of black and Hispanic middle school students in New York City report feeling unsafe in the classroom, than Asian and white students. Based on the estimates in this analysis, the achievement of a larger share of black and Hispanic students is negatively affected by feeling unsafe in the classroom, compared to their white and Asian peers. Although this is not proof that feeling unsafe directly contributes to educational inequality, it suggests that safety is one factor that systematically differentiates the academic success of black and Hispanic students. Ensuring that students feel safe in the classroom is a one step toward promoting educational achievement for all students. These findings also suggest that one place to start would be in schools that consistently report the highest violent and disruptive incident rates, where students experience the largest decline in test scores as a result of feeling unsafe in the classroom.

This analysis provides a strong case for the identification of a causal relationship, although some limitations remain. The effect of feeling unsafe on academic outcomes may be particularly salient for acute events, such as exposure to violent crime that causes a direct, yet potentially short-lived effect on both safety and academic performance. Acute effects are difficult to detect in this analysis due to the annual observation of feelings of safety, therefore these results likely reflect the cumulative effect of feeling unsafe at school over time. Also, the school survey data

provide detailed information about student perceptions of their environment that researchers generally do not have access to, but the questions about safety do not distinguish between physical safety and other types of safety, such as intellectual or emotional safety. The effect of safety on academic achievement may differ by type of safety, although I am unable to distinguish between these different types of safety in the student responses.

Finally, most research focused on a single city or a sample of students suffers from limited external validity. In this case, high coverage of the student population makes it possible to generalize from the results to all New York City middle school students. The sheer size and diversity of the New York City public school system provides ample variation in race, ethnicity, immigrant status, and other student factors, making lessons from New York relevant for other large urban schools systems. However, factors influencing safety may differ across other municipal contexts, and comparative work would benefit the field.

Policy Implications

This research has implications for four distinct areas of policy and programming aimed at improving safety in schools – accountability systems, classroom management, school-wide safety interventions, and district disciplinary policy.

First, accountability systems are used in many districts to measure the effectiveness of schools and teachers in promoting academic progress among students and reducing racial disparities in outcomes. In New York City, School Report Card grades account for aggregate school safety ratings and a "safe environment" is a category of evaluation during site visits for the Quality Reviews of all city schools. This research suggests that the student safety measures should carry larger weight in the Report Card grades and Quality Reviews, highlighting schools where students feel particularly unsafe. Classroom safety may also be an informative indicator

on teacher evaluations, signaling to principals that teachers with low reported classroom safety need training and support, and highlighting the classroom management strategies of teachers who succeed in creating safe classrooms.

Second, this research highlights the importance of school and classroom-level interventions that improve student safety. Several promising programs foster safety by addressing disciplinary problems in schools and classrooms, such as disruptive students or bullying. At the classroom level, "ecological" approaches to classroom management focus on improving the classroom setting to promote positive behavior, instead of focusing on particular students (Osher et al., 2010). One example is the Bridging Mental Health and Education in Urban Schools (BRIDGE) program, which aims to improve teacher interactions with all students in addition to those who exhibit behavioral problems. A random assignment study identifies improvements in teacher-student relationships, academic self-concept, and peer victimization for classrooms that received BRIDGE (Cappella et al., 2012). A review of the empirical literature on bullying interventions finds inconsistent results for curriculum-based interventions using videotapes, lectures, and written exercises, with most of the experimental studies showing no effect on bullying (Vreeman & Carroll, 2007). These studies suggest that curriculum-based programs alone, without classroom-management support for teachers, may be a less effective method for changing the classroom environment and influencing student behavior. Further, introducing new curricular units may take away from instructional time in core academic areas, while improving classroom management skills may allow teachers to dedicate more time to instruction.

Third, many interventions are staged at the school level in order to affect the broader school environment. Experimental research identifies two universal approaches to school discipline that improve student behavior: school wide positive behavioral supports programs, and social

emotional learning programs (Osher et al., 2010). Schoolwide positive behavioral supports programs focus on the school-based systems to prevent problem behavior, such as effectively communicating rules and rewarding positive behaviors. The results of a randomized trial suggest that students in schools with schoolwide positive behavioral supports programs are less likely to be referred to the principal's office than in comparison schools (Bradshaw, Mitchell, and Leaf, 2009). In contrast, social emotional learning programs target individual students and aim to build their self-awareness, social awareness, relationship skills, and decision making skills (Osher et al., 2010). Experimental studies of programs such as PATHS (Providing Alternative Thinking Strategies) and others document reductions in disruptive behavior and bullying where such programs are implemented (Osher et al., 2010). A study of a school-wide bullying intervention incorporating classroom programming, peer mediation, and student groups finds no effect on bullying but significant improvements in student reported feelings of safety (Rahey & Craig, 2002). Although the current findings suggest that safety in the classroom is the primary contributing factor to decreased test scores for students who feel unsafe, these studies suggest that select school-wide interventions may foster improvements in school climate, discipline, and student safety that may affect how students feel in the classroom.

Finally, across the country, many school districts including New York City have recently adopted changes to their school disciplinary codes in order to reduce the use of exclusionary disciplinary practices such as suspensions and to address racial disparities in school discipline. These policy changes include the creation of alternatives to "zero tolerance" policies, promotion of graduated sanction approaches to disciplinary problems, and use of suspensions for only the most serious offenses. Thus far there is little rigorous research investigating how disciplinary policies guiding suspensions affect student outcomes. Keeping "disruptive" students in the

classroom, instead of suspending them, may improve the individual student's academic outcomes (because he or she receives more instruction time), but it may be at the detriment of his or her peers (if the student continues to be disruptive, or requires the teacher to take time away from instruction). Changes in disciplinary policy may have important implications for student safety. Just as reducing suspensions may change the peer makeup of classrooms in ways that affect achievement for all students, the classroom environment may also be perceived as less safe by students. Alternatively, if school disciplinary policies are contributing to students feeling unsafe in the classroom – because they fear suspension or other punishment – then the policy changes may improve overall safety within classrooms.

Although disciplinary policies and practices surely play a role in generating fear or safety at school, other factors such as neighborhood violence or problems at home may cause some students to feel unsafe. The interventions described above may improve the classroom or school setting for all students, regardless of the source of their fear, but they are not targeted toward alleviating fear from outside sources. More research is needed to investigate contextual factors that mediate and/or moderate the impact of feelings of safety on academic outcomes, and to highlight schools that promote safety among students who are exposed to dangerous or disorderly environments, allowing them to excel academically.
